With the advancement of Lidar technology, bottom depth (H) of optically shallow waters (OSW) can be measured accurately with an airborne or space-borne Lidar system (H_{Lidar} hereafter), but this data product consists of a line format, rather than the desired charts or maps, particularly when the Lidar system is on a satellite. Meanwhile, radiometric measurements from multiband imagers can also be used to infer H (H_{imager} hereafter) of OSW with variable accuracy, though a map of bottom depth can be obtained. It is logical and advantageous to use the two data sources from collocated measurements to generate a more accurate bathymetry map of OSW, where usually image-specific empirical algorithms are developed and applied. Here, after an overview of both the empirical and semianalytical algorithms for the estimation of H from multiband imagers, we emphasize that the uncertainty of H_{imager} varies spatially, although it is straightforward to draw regressions between H_{Lidar} and radiometric data for the generation of H_{imager} . Further, we present a prototype system to map the confidence of H_{imager} pixel-wise, which has been lacking until today in the practices of passive remote sensing of bathymetry. We advocate the generation of a confidence measure in parallel with H_{imager} , which is important and urgent for broad user communities.

1. Introduction

The ocean depth is a geophysical property puzzling humans for thousands of years. The answer not only satisfies curiosity but also is important for many aspects of human activities and scientific studies, including navigation, ecosystem management, sustainable economic development, and ocean dynamic modeling [1]. To determine ocean bathymetry, the ancient Greeks (circa 80 BCE) used the “line sounding” method and obtained depth measurements up to ~2000 m in the Mediterranean Sea, while James Clark Ross obtained a depth of 4893 m in the 1840s. All these measurements were based on ship surveys; hence, it is unsurprising that the Challenger expedition (1872–1876), an oceanic voyage explicitly targeting ocean bathymetry, obtained just 492 soundings of the Atlantic Ocean. Only after the invention of Sonar during

World War II did great achievements occur in ocean bathymetry or bottom topography. Still, because the ocean bottom is covered by a thick layer of water, which is generally opaque to electromagnetic radiation, we still know much less about the seafloor compared to what we know about the surface of the Moon or Mars [2].

Since the launch and operation of satellites, our capability to observe and measure ocean bathymetry has significantly improved, where sea surface altimetry has been successfully used to indirectly infer the bathymetry [3, 4]. This approach cannot resolve small-scale variations and can only detect large seamounts that alter the earth’s gravitational field and subsequently the sea surface altimetry. One direct and precise measurement of bathymetry from airborne or space-borne platforms is Lidar (light detection and ranging) [5], which uses time lapses between emission and receiving of photons

interacting with the bottom (or a target) to calculate the distance photons traveled. This time-based technique can be used to accurately calculate the bottom depth of clear oceanic waters up to about 40 m at present [6, 7]. We commonly term this technique as active remote sensing of bottom depth and here use H_{Lidar} to represent the product obtained (see Table 1 for major symbols and acronyms used in this article). Although Lidar is only feasible for relatively shallow and clear waters, due to the significance of such regions, there are many airborne Lidar systems specifically developed for bathymetry [5, 8]. One extremely exciting and valuable development is the ICESat-2 satellite system [9], which sends out a laser at 532 nm, has a vertical resolution of about 0.17 m for bathymetry, and can potentially provide H_{Lidar} for various nearshore regions of the world [7]. This Lidar system, due to its space-borne nature, obtains measurements of mesh-style points (in the various lines dictated by the Lidar system and satellite orbit), not the desired bathymetry map.

A completely different approach of the optical measurement of bathymetry is based on radiative transfer, where a shallow bottom will affect the radiance emerging from below the sea surface. A quick and simple example is the shallow vs. deep ends of a swimming pool that appear as different colors to humans. Algorithms were then developed in the 1970s to use radiometric data from multiband imagers to estimate the bottom depth of shallow clear waters [10–12]. This image-based remote sensing of the bottom depth (H_{imager} hereafter) is commonly termed as passive remote sensing. Although such estimates of depth are not precise, a significant advantage is that a map of H_{imager} can be produced, especially with the launch and operation of more advanced sensors [1]. In recent decades, with an improved understanding of radiative transfer in optically shallow waters (OSW), more sophisticated algorithms based on radiative transfer were developed [13–19], resulting in the creation of more bathymetry maps from imagers [19–22]. For those algorithms based on the physics of radiative transfer, *a priori* depths are not required for the development of the algorithm, and H_{imager} can be produced as long as the input reflectance spectrum is highly reliable and has an adequate spectral resolution. However, since both the water and bottom properties affect the reflectance spectrum, there are still various uncertainties in the derived H_{imager} product from the reflectance spectrum.

In view of the availability of concurrent or collocated highly accurate satellite-based H_{Lidar} and high-spatial resolution multiband imagers, it is logical to develop schemes to generate bathymetry maps of OSW through the fusion of the two data sources [23, 24]. Figure 1 shows an example of measurements captured by ICESat-2 (red dashed line) and Landsat-8 operational land imager (OLI) over the Great Bahama Bank, where it is desired to expand the ICESat-2 bathymetry to the entire shallow regions covered by the Landsat-8 acquisition. As demonstrated in many studies, when collocated measurements of both H and radiometric properties are available, the generation of H_{imager} through explicit empirical regressions [25–28] or neural networks [29–31] becomes straightforward. However, these H_{imager}

TABLE 1: Major symbols and acronyms used in this article.

Symbol or acronym	Definition	Unit
$a(440)$	Total absorption coefficient at 440 nm	m^{-1}
H	Bottom depth	m
H_{Lidar}	Bottom depth measured by a Lidar system	m
H_{imager}	Bottom depth derived from an imager	m
ρ_{toa}	Top-of-atmosphere reflectance	—
R_{rs}	Remote sensing reflectance	sr^{-1}
$R_{\text{rs}}^{\text{mea}}$	R_{rs} from a measurement	sr^{-1}
$R_{\text{rs}}^{\text{mod}}$	R_{rs} from a model	sr^{-1}
$R_{\text{rs}}^{\text{ref}}$	R_{rs} in the matchup data pool	sr^{-1}
$R_{\text{rs}}^{\text{tar}}$	R_{rs} from a water target	sr^{-1}

OSW	Optically shallow water	
SAA	Semianalytical approach or algorithm	
TBRA	Two-band ratio algorithm	

products [25, 32] lack a representation of the confidence or quality of the product at each pixel, although schemes to estimate the impact of radiometric noise on H_{imager} have been developed [21, 33]. Usually, an averaged root mean square error or mean relative error of an algorithm is provided, but such measures of error represent the performance from a data pool and do not mean the same error or confidence at every pixel or location [34]. After the first demonstration of passive remote sensing of bottom depth [10, 12], what limited the broad-scale application of the H_{imager} product was not a lack of algorithms but rather the lack of a pixel-wise confidence measure for such products. Brando et al. [35] suggested using the closure between the measured and modeled remote sensing reflectance to infer the quality of H_{imager} . However, as this closure is an index for numerical solutions of a complex remote sensing function (see Section 2.3), a good closure does not necessarily indicate a high confidence of the derived H_{imager} . At present, the ability to generate a pixel-wise measure of the quality or confidence of H_{imager} through theoretical modeling is lacking, despite the necessity of such a measurement as it would vary spatially even within clear waters.

FIGURE 1: An example showing collocated measurements between Lidar and multiband imagers. The red dashed line shows a measurement track of ICESat-2, while the background image was captured by Landsat-8.

In this work, after review and demonstration of traditional passive schemes for bathymetry, we provide an original and novel prototype system to objectively classify the confidence of H_{imager} . We advocate the generation of such confidence products in parallel to remotely sensed bathymetry, where such a confidence measure would be essential to promote the use of H_{imager} by the broader community.

2. Overview of Passive Remote Sensing Algorithms for Shallow-Water Bathymetry

Detailed descriptions of the derivation of H from a Lidar system can be found in Guenther [5], where the key is to obtain precise measurements of time lapses of photons reflected by a sea bottom. For a water body with a shallow bottom, the remote sensing reflectance (R_{rs} , in sr^{-1})—the ratio of the radiance (L_w) emerging from below the surface to the downwelling irradiance just above the surface—can be expressed as [36–38]

$$R_{\text{rs}} = R_{\text{rs}}^{\text{dp}} \left[1 - e^{-(K_d + K_u^C)H} \right] + \frac{\rho}{\pi} e^{-(K_d + K_u^B)H}. \quad (1)$$

Here, $R_{\text{rs}}^{\text{dp}}$ is the remote sensing reflectance of the same water body but with no impact from the bottom (i.e., optically deep); ρ is the bottom reflectance modified by air-sea transmittance; K_d is the diffuse attenuation coefficient of

downwelling irradiance, with K_u^C and K_u^B for the diffuse attenuation of upwelling photons generated due to scattering in the water column and bottom reflection, respectively. $R_{\text{rs}}^{\text{dp}}$, K_u^C , and K_u^B can be parameterized with the water inherent optical properties [13, 36, 39]. Thus, while R_{rs} depends on the water optical properties and bottom reflectance, it is also a function of the bottom depth (H). Hence, various passive remote sensing algorithms have been developed to retrieve H from this spectral signal [11, 13, 21, 40]. These algorithms can be grouped into three approaches, two of which belong to the empirically based approach (EBA) and the other classed as a semianalytical approach (SAA). The following briefly describes the essence of these three schemes.

2.1. Explicit Empirical Approach (EEA)

2.1.1. Multiband Value Algorithm (MBVA). With collocated measurements of bottom depth and multiband radiometric data, Polcyn et al. [10] proposed the first empirical algorithm for H based on the difference between the shallow- and deep-water L_w , with the algorithm further refined by Lyzenga [12]. Generally, H_{imager} can be written as

$$H_{\text{imager}} = a_0 + a_1 Y(\lambda_1). \quad (2)$$

Here, Y is the logarithm of $(R_{\text{rs}} - R_{\text{rs}}^{\text{dp}})$ or $(L_w - L_w^{\text{dp}})$ and is calculated for a specific spectral band, while a_{0-1} are empirical coefficients tuned using collocated R_{rs} (or L_w) and H . This algorithm can be improved with the use of additional bands:

$$H_{\text{imager}} = a_0 + \sum_1^N a_i Y(\lambda_i). \quad (3)$$

N is the number of bands that are available and feasible from an imager; thus, there are $N + 1$ algorithm coefficients (a_{0-N}) to be tuned. Since Equations (2) and (3) are empirical, there is a potential that R_{rs} is smaller than $R_{\text{rs}}^{\text{dp}}$, e.g., over dark seagrass regions, which then causes an invalid mathematical calculation for Y ; this formula could be modified as [41]

$$H_{\text{imager}} = \alpha_0 + \sum_1^N \alpha_i \ln(R_{\text{rs}}(\lambda_i)). \quad (4)$$

Since bottom depth is related directly to the value of R_{rs} , we term this empirical model for H_{imager} as a multiband value approach (MBVA). Comparing Equation (4) with Equations (1)–(3), they are essentially the same, except that the Y (a difference between the shallow and deep regions in an image) in Equations (2) and (3) is replaced by R_{rs} in Equation (4).

2.1.2. Two-Band Ratio Algorithm (TBRA). Also, recognizing that the difference between R_{rs} and $R_{\text{rs}}^{\text{dp}}$ could be negative

over dark bottom substrates, Stumpf et al. [25] developed an empirical approach from the R_{rs} ratio of two bands to estimate H :

$$H_{\text{imager}} = m_0 + m_1 Z_{i-j}, \quad (5)$$

$$Z_{i-j} = \frac{\ln(3.14 n R_{rs}(\lambda_i))}{\ln(3.14 n R_{rs}(\lambda_j))}. \quad (6)$$

The three model coefficients ($n, m_{0,1}$) are also tuned using pairs of collocated R_{rs} and H . The value of n ranges 500-1500 and is usually fixed at 1000 [25, 42], while Traganos and Reinartz [34] indicated that a value of $n = 1.0$ works fine for a seagrass environment. As demonstrated in many studies [24, 25, 42], maps of bathymetry can be generated following this scheme. It is also possible to use the logarithm of the R_{rs} ratio from two bands for the empirical estimation of H [43]. However, Traganos et al. [41] found that the performance is worse than using the formulation given by Equation (5); hence, its discussion is omitted here. Because this approach employs a ratio of R_{rs} at two bands, we term this scheme a two-band ratio algorithm (TBRA), although Equation (5) can be expanded to include more available bands. The algorithms following Equations (2)–(5) are data-based (empirical), where algorithm relationships and coefficients are explicit, and the coefficients are driven by pairs of known H and R_{rs} . Note that if R_{rs} from more bands are required, it then places higher demands on atmospheric correction, especially in the longer wavelengths over optically shallow regions, where presently the OLI R_{rs} value in the red band sometimes is invalid.

2.2. Implicit Empirical Approach (IEA)

2.2.1. Estimation from R_{rs} . Different from the explicit empirical algorithms shown above, the machine learning approach (MLA, which in this manuscript collectively stands for neural networks, machine learning, and deep learning) is another data-based approach for the estimation of H from remote sensing measurements [29, 30, 44, 45]. Unlike EEA, the algorithm dependence or relationships and coefficients of MLA are hidden in the computer programming architecture (various layers and neurons), so it is not obvious how H_{imager} varies with R_{rs} or spectral radiance. As there are no explicit equations or parameters for such an approach; conceptually, the algorithm can be expressed as

$$H_{\text{imager}} = \text{MLA}_{R_{rs}}(R_{rs}(\lambda_i)). \quad (7)$$

Here, λ_i is the available and feasible band for the estimation of H (e.g., usually Bands 1-4 for Landsat-8 OLI), although there are no specific restrictions of R_{rs} that can be used.

2.2.2. Estimation from Top-of-Atmosphere Reflectance. Given that machine learning is empirical, another way to utilize MLA for H estimation is to bypass atmospheric correction [46], thereby estimating H and/or water properties directly

from the top-of-atmosphere reflectance (ρ_{toa}) [47]. Like Equation (7), this scheme can conceptually be defined as

$$H_{\text{imager}} = \text{MLA}_{\rho_{\text{toa}}}(\rho_{\text{toa}}(\lambda_i)). \quad (8)$$

To implicitly account for the contribution of atmosphere to ρ_{toa} , the range of λ_i will be from the visible to NIR-SWIR bands (e.g., Bands 1-7 for Landsat-8 OLI). Similar to the algorithms in Section 2.1, when sufficient pairs of H and ρ_{toa} are available, an $\text{MLA}_{\rho_{\text{toa}}}$ can be developed for the remote sensing of H_{imager} from ρ_{toa} . While an EEA like Equation (5) could be developed with 5-10 data points, an MLA requires much more data (usually hundreds or more) in the training phase. In addition, an MLA is much more complex in the computer architecture than the simple mathematical formulation presented in Equations (2)–(5).

2.3. Semianalytical Approach (SAA). A completely different set of algorithms for H is based on the radiative transfer equation. After parameterizing the spectra of inherent optical properties (IOPs) and bottom reflectance in Equation (1), an R_{rs} spectrum of shallow water could be simplified with five variables and expressed as [13]

$$R_{rs}(\lambda) = F(P, G, X, B, H). \quad (9)$$

Here, P and G represent the absorption coefficient of phytoplankton (a_{ph}) and detritus-gelbstoff (a_{dg}), X is the particle backscattering coefficient (b_{bp}), and B is the bottom reflectance, all set at a reference wavelength, such as 440 nm. The five variables can be solved numerically through spectral optimization (or minimization) by minimizing a cost function computed between the measured and modeled R_{rs} spectra, defined as

$$\text{err}_{R_{rs}} = \frac{\sqrt{\sum_1^N (R_{rs}^{\text{mod}}(\lambda_i) - R_{rs}^{\text{mea}}(\lambda_i))^2}}{\sum_1^N R_{rs}^{\text{mea}}(\lambda_i)}. \quad (10)$$

Provided there is a sufficient number of spectral bands and that the R_{rs} spectrum is in high quality, H_{imager} can be generated from image-based spectrometers without *a priori* data pairs of H and R_{rs} [35, 48, 49]. In addition, the bottom substrate class and water optical properties could also be generated from this process [14, 15, 19]. The SAA is extremely valuable to measurements that have R_{rs} only, but the retrievals depend on the quality of the R_{rs} spectrum and the number of spectral bands [21, 33, 35, 50]. For multiband imagery that has a limited number of spectral bands in the visible domain, such as Landsat-8 OLI and Sentinel-2 MSI, modifications on the SAA variables and processing are necessary [51]. Additionally, its computational load is significantly greater than that of EBA because an SAA solves 4-5 variables simultaneously for a given R_{rs} spectrum; fortunately, this demand can be met with greatly improved computer technology.

3. Data and Processing

Landsat-8 OLI and ICESat-2 measurements are used here to demonstrate H_{imager} maps from collocated Lidar data and multiband imagers and the generation of a pixel-wise H_{imager} confidence score.

3.1. Landsat-8 Data. Landsat-8 is an extension of the earlier Landsat series [52] and was launched on February 11, 2013. Its OLI has seven bands in the ~440–2200 nm domain to take measurements of the earth-atmosphere system. In particular, the spatial resolution of Landsat-8 OLI is 30 m, which provides detailed features of coastal regions where bottom depth can be highly heterogeneous. The Landsat-8 OLI Level-1 data processed by the Level-1 Product Generation System (LPGS) can be downloaded from the USGS website (<https://glovis.usgs.gov/>). The ρ_{toa} image data were processed using the SeaDAS package (v7.5) [53], and the atmospheric correction algorithm proposed by Bailey et al. [54] was adopted for the generation of R_{rs} . A low threshold of 0.0003 sr^{-1} is used for $R_{\text{rs}}(665)$ if it is found that the obtained $R_{\text{rs}}(665)$ is negative. Here, a few images over Florida Bay (24.76–24.89°N, 80.75–80.77°W; June 9 and October 15), the Great Bahama Bank (23.96–25.14°N, 76.80–76.93°W; March 7 and May 26), and the Great Barrier Reef (23.18–23.57°S, 151.68–151.93°E; August 8 and September 17) captured in 2019 were processed and utilized as examples.

3.2. ICESat-2 Data. ICESat-2 was launched on September 15, 2018. It is a follow-on mission to Ice, Cloud and land Elevation Satellite (ICESat) and provides global altimetry and atmospheric measurements with emphasis on surface elevation changes in polar regions [9]. The sole instrument onboard ICESat-2 is the Advanced Topographic Laser Altimeter System (ATLAS), a green (532 nm) wavelength, photon-counting laser altimeter with a 10 kHz pulse repetition rate [9, 55]. ATLAS uses photomultiplier tubes (PMTs) as detectors in the photon-counting mode so that a single photon reflected back to the receiver triggers a detection within the ICESat-2 data acquisition system. This single-photon-sensitive detection technique used by ATLAS to measure photon time of flight provides a very high vertical resolution required to detect small temporal changes in polar ice elevations [56, 57], as well as the bottom depth of optically shallow waters [7].

3.3. Data Matchup and Statistical Measures. Matchup datasets between the Landsat-8 OLI and ICESat-2 measurements were organized with the following processing steps: the Landsat-8 OLI pixels of dense clouds were first discriminated and removed based on the threshold of Rayleigh reflectance at the SWIR band (1238 nm) [58]. Meanwhile, the pixels of low-quality R_{rs} were removed based on the standard Level-2 quality flags included in SeaDAS, which include ATMFAIL (atmospheric correction failure), LAND (land pixel), CLDICE (probable cloud or ice contamination), HILT (very high or saturated observed radiance), and HIGLINT (strong sun glint contamination).

The ICESat-2 bathymetry results presented in this work use geolocated photon data, contained in the ATL03 data product, which are segmented into granules that span about 1/14th of an orbit [59]. Both OLI R_{rs} and ATL03 photon products include latitude and longitude information within the WGS-84 coordinate reference system.

Considering the variation of H (after tidal correction) is negligible within a short period, the time constraint for “concurrent” Landsat-8 OLI and ICESat-2 data is set as ± 2 weeks, and the ICESat-2 H product is adjusted to match the tidal cycle of Landsat-8, where the classical tidal harmonic analysis model T_TIDE was applied to calculate tide information of interested locations [60]. To match the measurement between ICESat-2 H and OLI R_{rs} , we first located the ICESat-2 track within the OLI image. For an ICESat-2 data point, a Landsat-8 pixel was first selected based on the closest distance. Since the spatial resolution of ICESat-2 along the orbit track is 0.7 m, while the footprint of OLI is 30 m, there are many ICESat-2 measurements within an OLI pixel. Therefore, for this OLI pixel, all ICESat-2 pixels within a radius of 15 m are used to calculate the mean H value and considered the matchup H_{Lidar} for this OLI R_{rs} .

To measure the deviation or error of the H_{imager} product, in addition to the coefficient of determination between any two sets of data, the root mean square error (RMSE) and the mean absolute relative error (MARE) between H_{imager} and H_{Lidar} are calculated:

$$\begin{aligned} \text{RMSE} &= \sqrt{\frac{1}{M} \sum_1^M (H_{\text{Lidar}} - H_{\text{imager}})^2}, \\ \text{MARE} &= \frac{1}{M} \sum_1^M \left| 1 - \frac{H_{\text{imager}}}{H_{\text{Lidar}}} \right|, \end{aligned} \quad (11)$$

where M is the total number of pairs used in the analyses. Note that the term “error,” rather than the term “difference,” is used in these analyses. This is because the uncertainty of H_{Lidar} is very low (a few centimeters); thus, H_{Lidar} could be considered the ground “truth,” and any difference between H_{imager} and H_{Lidar} will be most likely in the system to produce H_{imager} .

4. Predictability of Empirical Schemes

For a robust empirical scheme, the first aspect is to check if there are strong correlations between the input and the desired output, which is termed as predictability here and measured by the coefficient of determination in linear regression (R^2). A value of $R^2 = 1.0$ indicates a 100% predictability or certainty. For the case of bathymetry, the output is the bottom depth, while the input is the spectral information (spectra of ρ_{toa} or R_{rs} here) or value after its mathematical transformations (e.g., parameters Y or Z in Equations (2)–(5)). In the following, we use the compiled matchup datasets to show the different predictability of the abovementioned empirical schemes (TBRA, MBVA, $\text{MLA}_{R_{\text{rs}}}$, and $\text{MLA}_{\rho_{\text{toa}}}$).

TABLE 2: Values of R^2 between R_{rs} or ρ_{toa} and H_{Lidar} from a single Landsat-8 image (Great Bahama Bank, March 7, 2019), with the matchup H_{Lidar} in a range of ~ 1.5 – 9.0 m, and a total number of data pairs of 3512.

Algorithm type	Number of free variables in an algorithm	R^2	MARE	RMSE (m)
TBRA	2	0.36	0.16	1.02
MBVA	5	0.88	0.05	0.44
MLA $_{Rrs}$	1 hidden layer, 5 neurons	0.91	0.05	0.39
MLA $_{\rho_{toa}}$	1 hidden layer, 8 neurons	0.90	0.05	0.40
MLA $_{Rrs}$	3 hidden layers, 128, 32, and 16 neurons	0.97	0.04	0.33
MLA $_{\rho_{toa}}$	3 hidden layers, 128, 32, and 16 neurons	0.97	0.04	0.31

4.1. Predictability with Data from One Image. Many publications [24, 26, 41] have shown strong predictability ($R^2 \geq 0.86$) of EEA (TBRA or MBVA) for the estimation of H from R_{rs} . Such high predictability is not always the case [28] (also see Table 2). Figure 2 shows matchup measurements (>3500 pairs) over the Great Bahama Bank, an environment with generally clear water and shallow depths [43, 61, 62]. The OLI R_{rs} was obtained on March 7, 2019, where H_{Lidar} (obtained on March 16, 2019) ranges ~ 1.5 – 9.0 m after tide correction. The R^2 value between Z_{2-3} (for the R_{rs} ratio of OLI Band 2 and Band 3) and H_{Lidar} is ~ 0.36 (Figure 2(b)), which is dropped to ~ 0.20 when Z_{2-3} is changed to Z_{1-3} . These values indicate that such a ratio at most explained $<40\%$ of the variance for this dataset, although the radiometric measurements came from the same image, and that the distance of the points (see the red dashed line in Figure 2(a)) spans ~ 110 km. Most of the remaining variances ($>60\%$) are likely from the water column and bottom properties (i.e., assuming that uncertainties from sun-sensor geometry and atmospheric properties can be omitted), and these variations could not be resolved from Z_{2-3} . These R^2 values are significantly lower than those reported in previous studies [24, 26, 63], indicating a high data or environmental dependence of TBRA and its algorithm coefficients (m_{0-1}). The use of 20 or so data pairs to obtain a stable set of m_{0-1} [63, 64] will likely be a special case, rather than a common situation. This also echoes the findings of earlier studies [25, 27, 65] that one set of empirical coefficients cannot satisfy all pixels, even for the same image, unless the threshold for acceptable uncertainty is relaxed.

The R^2 value increases to 0.88 (Figure 2(c)) if MBVA (Equation (5)) is used to predict H_{Lidar} for the same dataset, indicating significantly higher predictability of MBVA for this dataset or environment. The results are even better (R^2 as 0.91), although not much, if an MLA with 1 hidden layer and 5 neurons (for an R_{rs} spectrum containing four visible bands) is used (Figure 2(d) and Table 2). These results highlight the importance of using more bands [66], explicitly (MBVA) or implicitly (MLA), to account for the likely changes of water properties and bottom substrates across an image.

In an MLA, each neuron is similar to a free variable in a multivariant nonlinear regression; thus, more free variables tend to improve regressions. For the MLA with 1 hidden layer and 5 neurons (for R_{rs}), the number of free variables is equivalent to that for MBVA; therefore, the results suggest

an improved capability of MLA to pick up hidden relationships between R_{rs} and H_{Lidar} . This predictability is further improved with a deep learning architecture of using 3 hidden layers and more neurons (see Table 2), indicating a great potential of machine learning for empirical estimation of bottom depth. Further, it is found that the statistical measures are nearly the same (see Table 2) between using R_{rs} (443–655 nm) and using ρ_{toa} (443–2200 nm) (1 hidden layer with 8 neurons, i.e., number of spectral bands plus 1) as the input to an MLA. These results suggest that through a nonlinear scheme like MLA, it is feasible to bypass the atmospheric correction step to retrieve H directly from the top-of-atmosphere measurements [46].

4.2. Predictability with Data from Multiple Images. To further observe the impact of data on the predictability of using two bands or multiple bands, especially the tolerance of MLA, a total of 5172 pairs of collocated Landsat-8 OLI and ICESat-2 data covering waters of the Bahamas (23.96–25.14°N, 76.80–76.93°W), Florida Bay (24.76–24.89°N, 80.75–80.77°W), and the Great Barrier Reef (23.18–23.57°S, 151.68–151.93°E) were compiled. For H_{Lidar} , corrected to match the tidal cycle of OLI measurements, in a range of ~ 1.0 – 11.0 m, TBRA, MBVA, and MLA produced R^2 values of 0.48, 0.84, and 0.91, respectively (see Table 3). MLA $_{\rho_{toa}}$ performs slightly better than MLA $_{Rrs}$ across these multiple images where there are various atmospheric properties, further supporting the concept of obtaining H_{imager} from ρ_{toa} when MLA is applicable. The improved predictability of MBVA and MLA is echoed by the MARE and RMSE values (see Tables 2 and 3), which are calculated after the model coefficients are determined through tuning or training. For instance, the MARE value is $\sim 10\%$ with RMSE as 0.54 m for MBVA, and MARE is $\sim 8\%$ with RMSE of 0.52 m for MLA. However, TBRA achieves a MARE value of 27% with RMSE as 1.25 m (see Table 3), which are about three times the values obtained using MBVA and MLA. These evaluations indicate improved predictability of using more bands, rather than using information from two bands, for the calculation of H_{imager} .

Such a result is expected because, as shown by Equation (9), R_{rs} of shallow water is governed by at least 4–5 variables; thus, a ratio of R_{rs} at two bands cannot resolve all unknowns, unless some of them are nearly constant or covarying with each other for a region of interest. However, even for this region in the Bahamas, as shown by Barnes et al. [61] and

FIGURE 2: Relationships between H_{Lidar} and radiometric measurements. (a) Measurement track of ICESat-2 (March 16, 2019) over a Landsat-8 image (March 7, 2019) in the Great Bahama Bank. (b) Relationship between H_{Lidar} and Z_{2-3} of the matchup data. (c) Relationship between H_{Lidar} and H_{imager} when MBVA is used for the empirical algorithm. (d) Relationship between H_{Lidar} and H_{imager} when MLA_{Rrs} is used for the empirical algorithm. The color coding in the scatterplots indicates the density of data points.

TABLE 3: R^2 values between R_{rs} or ρ_{toa} and H_{Lidar} from multiple Landsat images. Matchup H_{Lidar} is in a range of ~ 1.0 – 11.0 m, with 5172 data pairs.

Algorithm type	Number of free variables in an algorithm	R^2	MARE	RMSE (m)
TBRA	2	0.48	0.27	1.25
MBVA	5	0.84	0.10	0.54
MLA_{Rrs}	1 hidden layer, 5 neurons	0.91	0.08	0.52
$MLA_{\rho_{toa}}$	1 hidden layer, 8 neurons	0.92	0.08	0.51

Garcia et al. [62], their H , IOPs, and bottom substrates vary spatially. This is further evidenced by the spatial variation of $a(440)$ (see Figure 3) derived from HOPE for the matchup

data in Figure 2, where $a(440)$ varied from ~ 0.03 to 0.09 m^{-1} , showing limited correlation (R^2 as 0.18 and an inverse relationship) with H_{Lidar} . For such a wide variability in $a(440)$

FIGURE 3: Variation of $a(440)$ and H_{Lidar} along the ICESat-2 track in Figure 2.

(and no covariance with H), which plays a key role in the spectral variation of an R_{rs} spectrum, more bands and more free variables in an algorithm would improve the predictability. Note that $a(440)$ in Figure 3 is derived from HOPE with H fixed as H_{Lidar} from ICESat-2 (after tidal correction) and G fixed as 0.002 m^{-1} (see Section 5.2 for details), so the only variables are P , B , and X for Equation (9); therefore, the resulted P values (and then $a(440)$) are more reliable after the reduction of variables.

5. Applicability and Confidence Measure

The ultimate goal of any algorithm is to apply it to new measurements, i.e., data not used in the tuning or training, in order to obtain the desired remotely sensed product. While an empirical algorithm for H can be easily developed from collocated imagery and H_{Lidar} data, the extent that such an algorithm can be applied to new data is unknown. It has been demonstrated that the model coefficients (e.g., $a_{0,1}$ and $m_{0,1}$ in Equations (2)–(5)) developed from one image cannot be applied to another image if low uncertainties are the goal [26]. The scatter in the regression shown in Figure 2 indicates that these empirical coefficients may not be applicable even for locations within the same image, unless larger uncertainties are acceptable.

Conventionally, the applicability of an algorithm is assessed by evaluating its performance using an independent dataset, with the reported RMSE and/or MARE values as justifications [25–27]. It is necessary to keep in mind that such averages, although informative, are dependent on the data pool and do not represent the error or uncertainty of each pixel [34]. Because different users have different tolerance for the uncertainty of H_{imager} (e.g., high requirement of accuracy for navigation), the average error is insufficient to inform all users of H_{imager} . It is necessary and important to provide a confidence measure for H_{imager} products at each grid or pixel. The following addresses the confidence associ-

ated with both EBA and SSA, with a first-ever attempt to provide a pixel-wise confidence measure for H_{imager} .

5.1. Applicability of EBA and Measure of Confidence

5.1.1. Issues of the H_{imager} Map from Landsat-8 OLI. Following the practices commonly presented in the literature [23, 25], a map of 30 m resolution H_{imager} (see Figure 4) over the Great Bahama Bank was generated from a Landsat-8 OLI image (May 26, 2019) with a TBRA tuned using matchup data generated from this image and ICESat-2 bathymetry (May 25, 2019, the red dashed line in this map, and a total of 1707 pairs of data). As shown in the literature [23, 25] and as desired, the discrete or line-type bathymetry product from ICESat-2 is now expanded to form a bathymetry map. Overall, for the western side of Andres Island, Great Bahama Bank, the bottom depth ranged from ~ 2.0 to 8.0 m. This is consistent with our general understanding and depth retrievals from other observations and methods [61, 62, 67]. On average, the difference is $\sim 28.0\%$ when compared with that derived from MERIS [62], which is consistent with those reported in the literature [26, 28]. However, obviously, there are erroneous outputs, where the bathymetry is ~ 15.0 m for the Tongue of the Ocean (TOTO), which is known to be ~ 2000 meters deep. In other words, a “false positive” of the shallow bottom is derived from TBRA (similar “shallow bottom” for TOTO is also observed from MBVA and MLA, results not shown here). Such false positives can also be found in Caballero and Stumpf [26] for waters around Dry Tortugas, Key West (see Fig. 6d of Caballero and Stumpf [26]). These false positives are a result of the following two inherent limitations of empirical algorithms for H :

- (1) Empirical algorithms for H (e.g., Equations (2)–(8)) are developed using data from optically shallow waters, as only such data has an optical signal from the bottom

FIGURE 4: Bathymetry map for the image shown in Figure 1 obtained through the fusion of ICESat-2 H_{Lidar} and Landsat-8 radiometric measurements. Grey and white colors represent land and cloud or nonvalid R_{rs} , respectively. The red dashed line is the measurement track of ICESat-2.

- (2) By design, the empirical algorithm is data-driven; i.e., it can only be applied to measurement with similar characteristics as the training data

When an EBA, such as the TBRA, is applied to multiband imagery, however, these two basic requirements or assumptions are hardly tested or evaluated *a priori*. In other words, an H_{imager} map was generated by assuming, blindly, the algorithm is applicable to any R_{rs} in an image used during the algorithm tuning. Consequently, an erroneous bottom depth over TOTO was generated (see Figure 4). For this image, we know TOTO is optically deep, so such false products can be easily ignored or masked out. However, not all locations or pixels within an image do we know *a priori* their optical properties; thus, it is not certain if the environment is optically shallow or not. Therefore, it is not straightforward to mask out optically deep waters with empirical algorithms such as Equations (2)–(8). As such, usually, the resultant H_{imager} of deeper depths were manually, and arbitrarily, masked out (e.g., [68]).

5.1.2. Criteria to Check the Applicability of an Empirical Algorithm for H_{imager} . To confidently apply an EBA H_{imager} algorithm to a new R_{rs} spectrum, to the least, it is important and necessary to check if the R_{rs} from this target location meets the following two criteria:

- (1) *Criterion 1 (Cr1)*. If it is optically shallow; and
- (2) *Criterion 2 (Cr2)*. If there is an identical or similar R_{rs} spectrum in the training pool.

Such two criteria are omitted or ignored at present in the practices related to EBA for H_{imager} , although an SAA can separate optically deep vs. optically shallow during data processing [20, 35].

Given that the EBA formulation for deriving depth cannot provide information on whether a pixel is optically

FIGURE 5: Classification of optically shallow waters (red color) with a neural network scheme. Blue, grey, and white colors represent optically deep waters, land, and cloud or nonvalid R_{rs} , respectively. There are more white pixels than in Figure 4, which is a result of negative or no R_{rs} data at 561 or 655 nm.

deep or shallow, a neural network (NN_{OSW}) based on Multi-layer Perception (MLP) was developed to aid in the determination of *Cr1*. MLP is a class of feedforward artificial neural networks (ANN) composed of one input layer, one or multiple hidden layers associated with one output layer. Since here Landsat data are used, values of $R_{\text{rs}}(443)$, $R_{\text{rs}}(482)$, $R_{\text{rs}}(561)$, and $R_{\text{rs}}(655)$ are the input, while the output is optically deep (assigned a value of 0) or shallow (assigned a value of 1). The number of hidden layers and the number of neurons of each layer were determined following the concept of minimum loss, a common approach for developing a deep learning system. Data used for the training came from known optically deep (Landsat measurements in Massachusetts Bay, Chesapeake Bay, and TOTO) and optically shallow (Great Bahama Bank, Florida Keys) environments. After many training attempts, two hidden layers with 32 and 16 neurons were found to provide the best performance for this separation. Separately, the *Rectified Linear Unit* (ReLU) function for the activation function of hidden layers is employed, which can largely avoid gradient disappearance. Since it is binary classification, the activation function of the output layer is a *Sigmoid* function. The training stage was eventually achieved when the iteration is stopped, and the loss function converges. Figure 5 shows an example of the OSW classification after applying NN_{OSW} to the Landsat-8 OLI image displayed in Figure 1. Although the deep vs. shallow separation may not be perfect at this stage, waters of TOTO are optically deep and clearly separated. Since all neural network-based algorithms are data-driven, we envision that this initial NN_{OSW} will be updated after more optically deep and shallow data are employed.

Further, a similarity index ($\text{SIM}_{R_{\text{rs}}}$) is designed for *Cr2*, such that the higher the $\text{SIM}_{R_{\text{rs}}}$ value, the higher the measure of similarity; therefore, the target R_{rs} spectrum is likely

FIGURE 6: Variation of H_{Lidar} and ARE_H along the ICESat-2 track in Figure 1.

“learned” in the phase of algorithm development. In this effort, $\text{SIM}_{R_{rs}}$ is defined and calculated as follows.

A target R_{rs} spectrum (R_{rs}^{tar}) is evaluated against each R_{rs} spectrum in the training pool ($R_{rs}^{\text{ref}(j)}$):

$$\text{MARD1}_{R_{rs}}(j) = \frac{1}{N} \sum_{i=1}^N \left| 1 - \frac{R_{rs}^{\text{tar}}(\lambda_i)}{R_{rs}^{\text{ref}(j)}(\lambda_i)} \right|, \quad (12)$$

$$\text{MARD2}_{R_{rs}}(j) = \frac{\sum_{i=1}^N |R_{rs}^{\text{tar}}(\lambda_i) - R_{rs}^{\text{ref}(j)}(\lambda_i)|}{\sum_{i=1}^N R_{rs}^{\text{ref}(j)}(\lambda_i)}. \quad (13)$$

Here, $\text{MARD}_{R_{rs}}$ represents a mean absolute relative difference between two R_{rs} spectra, with j for the j th R_{rs}^{ref} . The calculations of Equations (12) and (13) show two ways of quantifying MARD, where a small difference in R_{rs} at a single band plays a bigger role for $\text{MARD1}_{R_{rs}}$, while it is the large value in R_{rs} that plays a larger role for $\text{MARD2}_{R_{rs}}$. Since there are many $R_{rs}^{\text{ref}(j)}$ in the data pool (1707 pairs in this case), many $\text{MARD1}_{R_{rs}}$ and $\text{MARD2}_{R_{rs}}$ values for a given R_{rs}^{tar} will be obtained; the minimum of the combination of $\text{MARD1}_{R_{rs}}$ and $\text{MARD2}_{R_{rs}}$ is selected for the quantification of $\text{SIM}_{R_{rs}}$, calculated as

$$\text{SIM}_{R_{rs}} = 1 - \min \left\{ (0.5 \text{MARD1}_{R_{rs}}(j) + 0.5 \text{MARD2}_{R_{rs}}(j)) \right\}, \quad \text{within all } R_{rs}^{\text{ref}(j)}. \quad (14)$$

The use of 50% for both $\text{MARD1}_{R_{rs}}$ and $\text{MARD2}_{R_{rs}}$ is a compromise between the two ways of evaluating spectral differences.

5.2. Confidence Score System for H_{imager} . We thus propose to use this similarity measure to gauge the likely quality of H_{imager} . For instance, if $\text{SIM}_{R_{rs}} = 1.0$ for an R_{rs}^{tar} , it indicates that there is an identical R_{rs}^{ref} in the training pool. Further, we know the absolute relative error of H (ARE_H) for each

H_{imager} in the data pool (see Figure 6 for example); thus, an identical ARE_H for this R_{rs}^{tar} is expected from that for R_{rs}^{ref} , which can be found in the data pool. Therefore, based on the value of ARE_{H_p} , the confidence or quality of each H_{imager} can be classified as detailed below. Here, ARE_H is calculated as

$$\text{ARE}_H = \frac{|H_{\text{imager}} - H_{\text{Lidar}}|}{H_{\text{Lidar}}}. \quad (15)$$

While a low $\text{SIM}_{R_{rs}}$ value indicates low confidence in H_{imager} (i.e., R_{rs}^{tar} is likely out of the data range in training), a high $\text{SIM}_{R_{rs}}$ value is not automatically a guarantee of high confidence or high accuracy of H_{imager} . As shown in Figure 6, although the mean of the ARE_H is $\sim 5\%$ (R^2 value is 0.69 between H_{imager} and H_{Lidar}) for the entire dataset, it does not suggest it is 5% for each point. For some data points, the ARE_H could be as high as 20%. Thus, if this R_{rs}^{tar} matches the R_{rs}^{ref} having an ARE_H of 20%, the H_{imager} of this R_{rs}^{tar} is expected to have such a relative error from this algorithm.

Following the above indications, we designed a preliminary confidence score system (CSS) based on both $\text{SIM}_{R_{rs}}$ and ARE_H in the data pool to classify the quality of the H_{imager} product. At this initial stage, this CSS is designed to coarsely classify the confidence of H_{imager} into three classes: low (score = 1), medium (score = 2), or high (score = 3), which is determined based on a decision tree (see Figure 7 for details). With this tree, H_{imager} from an R_{rs}^{tar} spectrum having both high $\text{SIM}_{R_{rs}}$ values and low ARE_H values can be considered to have high confidence.

Figure 8 shows a map of confidence for the H_{imager} product presented in Figure 4. Generally, for pixels not too far from the track of ICESat-2 and with depths ~ 6.0 – 8.0 m, the confidence of H_{imager} is high, a result of similar characteristics in the R_{rs} data and the environment that were used in the training. For pixels near the coast of Andros Island and those

FIGURE 7: Decision tree to determine the confidence score of H_{imager} obtained through an empirical algorithm.

FIGURE 8: Confidence score map for the H_{imager} product shown in Figure 4. The black dashed line is the measurement track of ICESat-2 on March 16, 2019, where H_{Lidar} is used as independent measurement to evaluate the confidence map.

in the Exumas region (east of TOTO) where the retrieved H_{imager} is generally under ~ 4.0 m, the confidence of H_{imager} is low. This is because the data pool used to develop the empirical algorithm has a depth range of ~ 5.0 – 8.0 m (see Figure 6); thus, this empirical algorithm did not “learn” the spectral characteristics of R_{rs} of depths shallower than ~ 4.0 m or with very different bottom and/or water properties (see Figure 3 for the wide variation of $a(440)$). This low confidence is further confirmed using H_{Lidar} obtained on March 16, 2019 (the black line in Figure 8). After adjusting the tidal cycle to match the image time of May 26, 2019, and assuming no significant changes of bottom topography in the past ~ 70 days, it was found that ARE_H is generally around 40% or more (see Figure 9), above the 25% criterion of low confidence. The overall accuracy of classifying low-confidence pixels is 80.2%, while the accuracy of classifying medium- and high-confidence pixels is $\sim 1\%$. This extremely low accuracy for medium- to high-confidence pixels is due to the low number of such data points (see Figure 3), thus statistically not significant. The less than perfect classification result, in part, results from a few (~ 200) measurements where H_{Lidar} values are less than 4.0 m, but the ARE_H values for these points are under 10%; i.e., they belong to the high-confidence category. This excellent performance of TBRA for these pixels deserves further studies as the range of H_{Lidar} used in TBRA development was ~ 5.0 – 8.0 m (see Figure 6). Nevertheless, these results (Figures 6, 8, and 9) highlight that, unlike Sonar- or Lidar-produced H where

the uncertainty in H measurement is generally uniform, the uncertainty or confidence of the H_{imager} product is far from uniform [34]; thus, it is important and necessary to have a pixel-wise measure of the quality of H_{imager} . Further, the $>80\%$ success rate suggests that the CSS does provide a good indication of the confidence of H_{imager} , although there is room for improvement.

Caballero and Stumpf [26] suggested the use of multiple acquisitions to measure the performance of an algorithm, with an assumption that bottom depth should remain the same (after tidal correction) for a short period of time. These multiple observations are useful and important [51], but they may not overcome systematic biases embedded in an empirical algorithm. One example is the “shallow bottom” of TOTO (Figure 4); such “shallow bottom” will repeat itself when similar empirical algorithms are applied to new multi-band images.

5.3. Applicability of SAA

5.3.1. Example of H_{imager} from Landsat-8 OLI. SAA is not data-driven; its applicability is dependent on the R_{rs} spectrum itself, as well as the bio-optical models and the simplified expression for R_{rs} [13, 21, 35, 50]. As articulated in many studies, SAA requires a highly accurate R_{rs} spectrum as input, as errors in R_{rs} will be propagated into the retrieved IOPs and/or H_{imager} [21, 33, 35]. While empirical algorithms can overcome some systematic errors in R_{rs} in the tuning or training phase, SAA, at least in its present form, cannot. In addition, the number of wavelengths plays an important role in the retrieval of H [50]. This is because, within an SAA, the IOPs and bottom properties are assumed independent variables, while empirical algorithms (especially MLA) may find, and remedy to some extent, some hidden relationships among them and therefore transfer systematic bias or relationships into the algorithm coefficients (explicitly or implicitly).

To demonstrate the retrieval of H_{imager} from Landsat-8 OLI data with an SAA, the default HOPE algorithm was applied to the data pairs shown in Figure 2(a) (the red line), a data pool of a wide range of bottom depths (H_{Lidar} is ~ 1.5 – 9.0 m) and dynamic water properties ($a(440)$ is in a range of ~ 0.03 – 0.09 m^{-1}). Because Landsat-8 OLI has only four usable bands for shallow-water remote sensing (the 865 nm has nearly no information of the water and bottom for most

FIGURE 9: Evaluation (represented by ARE_H) of H_{imager} shown in Figure 4 using independent H_{Lidar} (the black dashed line in Figure 8), along with a corresponding confidence score (QS). Note that to remove the noises in the Landsat-8 product (resulted in spikes in ARE_H), a median filter with a window size of 21 was applied to H_{imager} before the calculation of ARE_H .

FIGURE 10: (a) Variation of H_{Lidar} and H_{imager} for the ICESat-2 track in Figure 2(a). (b) Scatterplot between ARE_H and err_{Rrs} of this dataset, with the color coding indicating the density of data points.

water bodies), Equation (9) is underdetermined. Considering that the spectral shapes of a_{ph} and a_{dg} in the 440–561 nm range are similar, and that a_{ph} and a_{dg} do not make significant contributions to the total absorption at 561 nm, here, G in Equation (9) was fixed as 0.002 m^{-1} in order to process Landsat-8 R_{rs} , and this modified version is termed as HOPE_{LS8} . This fixed G value of 0.002 m^{-1} is simply a reflection that for waters in this region, it is close to the lowest value for a_{dg} (440) [61]. Also, note that HOPE_{LS8} is certainly subject to refinement, but that is not the focus here.

Figure 10(a) compares the profiles of H_{imager} from HOPE_{LS8} with H_{Lidar} from ICESat-2, which are two independent determinations, and an R^2 value of 0.66 was obtained. Figure 10(a) also shows the profile of ARE_H for each pair, which ranges from 0.2 to 100%, with a median value of 17.7%. Although a generally consistent bathymetry pattern of H_{imager} from HOPE_{LS8} is obtained, these statistical measures do suggest that substantially more effort is required if high-confidence H_{imager} is to be retrieved by HOPE_{LS8} from such multiband R_{rs} .

There could be many sources contributing to the moderate performance in the retrieved H_{imager} . These include the sensor's calibration, the atmospheric correction, the bio-optical models used in HOPE_{LS8} , or the number of available bands. It is not the scope of this effort to address the impact of those elements and the refinement of HOPE_{LS8} , where algorithm improvement is constantly ongoing. Here, we focus on the necessity and development of a CSS to measure the pixel-wise confidence of H_{imager} retrieved from an SAA (such as HOPE_{LS8}). Brando et al. [35] developed a system to classify the quality of H_{imager} into two categories (good or bad) based on the err_{Rrs} value (Equation (10)) and assumed that H_{imager} has high confidence when a low err_{Rrs} value (i.e., good closure between the measured and modeled R_{rs} spectra) is obtained. However, err_{Rrs} is determined by various components and many sources; there could be the same err_{Rrs} but with different H results. For instance, when the bio-optical models are modified, a different H_{imager} would be retrieved, but the value of err_{Rrs} can remain the same. Thus, as demonstrated in Figure 10(b) and previous studies

FIGURE 11: Decision tree to determine the confidence score of H_{imager} obtained through a semianalytical algorithm.

FIGURE 12: (a) As Figure 4, the H_{imager} map obtained from Landsat-8 OLI R_{rs} after applying HOPE_{LS8} . (b) Confidence score map for the H_{imager} product shown on the left. Grey color for land, and white for cloud or nonvalid R_{rs} .

[13, 35, 49], there is no relationship between $\text{err}_{R_{\text{rs}}}$ and ARE_H (R^2 is ~ 0.1); thus, $\text{err}_{R_{\text{rs}}}$ is insufficient to indicate the quality of H_{imager} when it is retrieved with an SAA. A small $\text{err}_{R_{\text{rs}}}$, by its definition, indicates only a high agreement between the measured and modeled R_{rs} spectra.

5.3.2. Confidence Score System for SAA-Derived H_{imager} . Following the CSS scheme for EBA, a prototype CSS for H_{imager} from HOPE (CSS_{HOPE}) was also developed and presented in Figure 11. Since an SAA determines a set of solution using $\text{err}_{R_{\text{rs}}}$, a first-order decision could be based on the value of $\text{err}_{R_{\text{rs}}}$ [13, 35]. If the $\text{err}_{R_{\text{rs}}}$ value is higher than a threshold, it indicates that the closure between the input and output R_{rs} spectra is not enough; thus, the retrieved H_{imager} could be questionable [13, 35]. Here, we tentatively set this threshold for $\text{err}_{R_{\text{rs}}}$ as 0.02, as most $\text{err}_{R_{\text{rs}}}$ values are found smaller than this value (see Figure 10(b)) for the data pool shown in Figure 2. When there are no collocated and reliable H data available, the maximum relative contribution from the bottom to the total R_{rs} is used as an indicator to gauge the confidence of estimated H_{imager} [20, 35]. Too low a value (usually the threshold is 20% [20]) suggests a low contribution from the bottom and low confidence of retrieved bottom properties [35]. Since there are matchups between R_{rs} and H_{Lidar} ,

the CSS developed for EBA could be employed for pixels with $\text{err}_{R_{\text{rs}}}$ values below the threshold, as illustrated in Figure 11. Thus, for H_{imager} derived from HOPE_{LS8} , a companion confidence score could also be produced.

As an example, Figure 12 shows a map of H_{imager} obtained from HOPE_{LS8} (Figure 12(a)) and its confidence map (CSS_{HOPE} , Figure 12(b)). Similar to the bathymetry map obtained from TBRA, the depth in the west of Andros Island obtained from HOPE_{LS8} also has a range of ~ 4.0 – 8.0 m, a generally consistent pattern as observed before. For waters of the TOTO, the H_{imager} map shows a depth of 20 m, which is basically the upper boundary preselected within the HOPE_{LS8} system, where actually the contribution from the bottom is negligible when processed with HOPE_{LS8} , so it can be easily marked as optically deep water as in Lee et al. [20] and Brando et al. [35]. More importantly, the pixel-wise quality of H_{imager} (CSS_{HOPE}) shown in Figure 12(b) provides a clearer indication of the confidence on the H_{imager} product pixel by pixel. Similarly, as Figure 8, higher confidence of H_{imager} is found for pixels around the ICESat-2 track, and low confidence is found for locations near the coast. Evaluation using H_{Lidar} (March 16, 2019) (the black dashed line in Figure 12(b)) indicates a success rate of $\sim 99\%$ in identifying low-confidence pixels. In addition,

there are differences in the distributions of confidence between the two H_{imager} products (see Figures 4 and 12), a clear indication of the performance of different approaches for bathymetry. On the other hand, because H_{imager} from an SAA (e.g., HOPE_{LS8} here) is an independent determination of H from that of H_{Lidar} , SAA offers an opportunity to check consistency from the two measurements, which is not possible with EBA.

6. Conclusions and Future Perspective

Through many decades of effort, there is no shortage of remote sensing products from multiband or hyperspectral imagers, but there is a shortage of remote sensing products attached with a confidence measure; this is especially true for the remote sensing of bathymetry. Compared to active measurements of bottom depth by Sonar or Lidar, the retrieved H_{imager} is still facing difficulties in its applications by the broader community, where a key limiting factor until now is the lack of pixel-wise confidence for the H_{imager} product.

To fill this void, a prototype confidence score system (CSS) for H_{imager} is proposed for the first time, which at present classifies all pixels in an H_{imager} map of OSW into three categories: low, medium, and high, with a preliminary set of criteria. Since this CSS involves both the algorithm coefficients and the data used for the development of empirical algorithms, it is logical that not only the algorithm function and model coefficients be reported but also the data pool used for the algorithm development be deposited in a common data portal. In the future, while it is always necessary and important to continue the refinement of these algorithms, it is also important, and urgent, to develop or revise or refine such system(s) to measure the confidence of the resulting H_{imager} pixel by pixel. Specifically, it includes a refinement of the quality classes, thresholds, and settings of the criteria, as well as the desired statistical measures. Only the H_{imager} product of high confidence from multiple images could be merged to form a reliable map for the broad user communities. We call on the ocean color community to refine such schemes or to develop brand-new systems, so a mature and widely endorsed system could be implemented to clearly measure the quality of H_{imager} , a critical parallel product of remotely sensed bathymetry. To reach this goal, it is also urgent and important to compile, by the community and for the community, an inclusive data pool of collocated or concurrent measurements of H_{Lidar} and high-quality ρ_{toa} and R_{rs} spectra of a wide range of depths and environments.

Data Availability

The satellite data used to support the findings of this study are publicly available. Landsat-8 data can be downloaded from the USGS website (<https://glovis.usgs.gov/>), while ICESat-2 data can be downloaded from the National Snow and Ice Data Center (NSIDC), where the geolocated photon data (ATL03) can be found online at <https://nsidc.org/data/atl03>.

Conflicts of Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Authors' Contributions

ZL conceptualized the study and drafted and finalized the manuscript; MS helped in analyzing Lidar data; RG helped in Landsat-8 data processing and finalizing the manuscript; WL developed machine learning algorithms; XL helped in ICESat-2 data processing; JW processed Landsat-8 data; XY helped in data matching and empirical algorithms.

Acknowledgments

Financial support by the Chinese Ministry of Science and Technology through the National Key Research and Development Program of China (#2016YFC1400904 and #2016YFC1400905) and the National Natural Science Foundation of China (#41941008, #41890803, and #41830102), the Joint Polar Satellite System (JPSS) funding for the NOAA ocean color calibration and validation (Cal/Val) project, and the University of Massachusetts Boston is greatly appreciated. The authors would like to thank the NASA ICESat-2 team for providing the data used in this study. The ICESat-2 data are publicly available through the National Snow and Ice Data Center (NSIDC). The geolocated photon data (ATL03) are found online (<https://nsidc.org/data/atl03>), with descriptions that can be found in the cited reference of Neumann et al. [60].
