We report a leukocyte membrane-coated gallium nanoswimmer (LMGNS) capable of ultrasound-propelled motion, antibiofouling, and cancer cell recognition and targeting. The LMGNS consists of a needle-shaped gallium core encapsulating an anticancer drug and a natural leukocyte membrane shell. Under the propulsion of an ultrasound field, LMGNSs could autonomously move in biological media with a speed up to $108.7 \mu\text{m s}^{-1}$. The velocity and motion direction of the LMGNSs can be modulated by regulating the frequency and voltage of the applied ultrasound field. Owing to the leukocyte membrane coating, LMGNSs can not only avoid biofouling during the motion in blood but also possess cancer cell recognition capability. These LMGNSs could actively seek, penetrate, and internalize into the cancer cells and achieve enhanced anticancer efficiency by combined photothermal and chemical therapy. Such biofunctionalized liquid metal nanoswimmer presents a new type of multifunctional platform for biomedical applications.

1. Introduction

Nanoswimmers, which convert diverse types of energy into mechanical movement [1–5], hold great promise in providing solutions to various future technological needs, such as controlled capture [6, 7], electronic repair [8], environmental remediation [9, 10], and complex microstructure fabrication [11, 12]. In particular, synthetic nanoswimmers may perform diverse operations in the biomedical field, including biosensing [13, 14], diagnostics [15, 16], precision surgery [17], laser tissue welding [18], and direct drug delivery [19, 20]. In recent years, various strategies have been employed to propel such micro/nanoswimmers, including chemical reaction [21, 22], light stimuli [23–25], and electric [26, 27], magnetism [28, 29], and acoustic [30, 31] actuation. However, most of the nanoswimmers still rely on inorganic materials, such as SiO_2 , mesoporous silicon, and Fe_3O_4 ; these formulations often fail to be useable in the biosystem for the systemic toxicity or poor biodegradability.

Liquid metal, a biofriendly material with excellent properties including low melting point, large surface tension,

and high thermal and electric conductivity [32–34], has emerged for stretchable electronics and soft robots [35–39]. In our previous work [40], we demonstrated a first example of the soft rod-like liquid metal nanoswimmers which could transform from rod to droplet, fuse together, and be degraded in both an acidic buffer and biomedium of cancer cells. To date, gallium-based liquid metal has aroused great interest in the field of biomedicine [41–43]. However, it is still a challenge to fabricate liquid metal-based nanoswimmers with the capability of active motion, antibiofouling, and targeted drug delivery.

Here, we demonstrate an acoustically propelled leukocyte membrane-coated gallium nanoswimmer (LMGNS), which can be served as a multifunctional platform for precise cancer therapy, as shown in Scheme 1. The biomimetic nanoswimmers were fabricated by combining the pressure-filter-template method [40] and cell membrane-cloaking technique. The as-fabricated LMGNS has a needle-like structure, thus displaying autonomous motion under the propulsion of the ultrasonic field. The velocity and direction of the LMGNSs can be regulated by alternating frequency and

SCHEME 1: The acoustically propelled leukocyte membrane-coated gallium nanoswimmers (LMGNSs) actively target, penetrate, and kill the cancer cell.

voltage of the ultrasound field. Moreover, the LMGNSs have the capacities of antibiofouling, prolonged motion in biological medium, and recognition of cancer cells. LMGNSs could also actively target and penetrate the predefined cancer cells. With the combination of photothermal therapy and targeted drug delivery, LMGNSs display enhanced anticancer efficacy.

2. Results and Discussion

As demonstrated in Figure 1(a), to synthesize the leukocyte membrane-coated gallium nanoswimmers (LMGNSs), gallium nanoswimmers (GNSs) were firstly fabricated by using the previously reported pressure-filter-template method [40]. The scanning electron microscopy (SEM) image shows that the obtained GNSs displayed a needle-like shape, with a length of $7.03 \pm 0.60 \mu\text{m}$ and a diameter of $800 \pm 51 \text{ nm}$ and $153 \pm 37 \text{ nm}$ at each end (Figure 1(b)). The transmission electron microscopy (TEM) image demonstrates that GNS has a core-shell structure, and the thickness of the shell was about 8 nm (Figure 1(c)). EDX mapping analysis shows that the GNSs were composed by the gallium and oxygen elements, indicating that the shell was Ga_2O_3 (Figure S1). In order to load the anticancer drug, aminopropyltrimethoxysilane (APTMS) and carbonylated β -cyclodextrin (β -CD) were modified onto the shell of GNSs. After modification, Fourier transform infrared (FTIR) spectra show that GNSs presented new characteristic peaks at 2950 cm^{-1} , 1565 cm^{-1} , 1000 to 1100 cm^{-1} , and 1677 cm^{-1} , which may correspond to the stretching vibration of C-H, the bending vibration of N-H, the Si-O bond from APTMS, and the stretching vibration of the C=O group from carbonylated β -CD, respectively (Figure 1(d)). The X-ray photoelectron spectroscopy (XPS) spectrum in Figure 1(e) shows the three subcomponent peaks of O 1s with binding energies at 530.8 eV (Ga_2O_3), 531.2 eV (C=O), and 532.1 eV (C-O-C). And Figure S2 demonstrates the two states of nitrogen at 398.7 eV (C-N) and 399.7 eV (C-N-C). These results suggest that aminopropyltrimethoxysilane and

carbonylated β -CD were successfully modified onto the surface of GNSs.

After that, leukocyte membrane vesicles were isolated through a physical extrusion procedure [44] and then were fused onto the surface of GNSs through an acoustically assisted nanovesicle fusion method, as shown in Figure S3. Then, the structure of the LMGNSs was studied by using confocal laser scanning microscopy (CLSM), in which the leukocyte membranes were labeled with 1,1'-dioctadecyl-3,3,3',3'-tetramethylindodicarbocyanine (DiD) before fusion. CLSM images show that the green fluorescence displayed a high degree of colocalization with the red fluorescent signals (Figure 1(f)). It can be confirmed that the green fluorescence excited by a 488 nm light came from GNSs. However, the source of the red fluorescence is uncertain, because the GNSs also could display red photoluminescence under the irradiation of a certain intensity of 633 nm light [40]. Thus, we analyzed the CLSM images of GNSs and LMGNSs excited by 633 nm light at different intensities. As shown in Figure S4, only the LMGNSs showed noticeable fluorescence at the same laser intensity as in Figure 1(f) (4 mV), indicating that the red fluorescence came from the DiD-labeled leukocyte membrane. We also found that the zeta potential changed from -13.1 mV (GNSs) to -22.9 mV (LMGNSs), which is similar to the value of a leukocyte membrane (Figure 1(g)). Taken together, these results demonstrate that leukocyte membrane vesicles fused onto the surface of GNSs and LMGNSs were successfully fabricated.

Then, these LMGNSs were explored to transport anticancer drugs, and their drug-loading capacity was evaluated, in which doxorubicin (Dox) was chosen as a model drug. After being loaded with Dox, a characteristic absorption peak of Dox at 480 nm was found, indicating the successful encapsulation of Dox (Figure 1(h)). The Dox-loading rate was determined by measuring the mass of nanoswimmers before and after Dox encapsulation. We found that the mass of LMGNSs before and after encapsulation was 5.3 and 6.1 mg, respectively, which indicates that the Dox-loading capacity was

about 13.1%wt. The Dox release profiles of GNSs-Dox and LMGNSs-Dox were evaluated through the dialysis method in the PBS buffer with the pH of 5.0 and 7.4. The released Dox from GNSs-Dox and LMGNSs-Dox in the acidic buffer was 47.4% and 72.6% within 4 h, respectively; however, there were only 5.3% and 17.7% in the neutral buffer, respectively (Figure 1(i)). The differences in released amount between GNSs-Dox and LMGNSs-Dox at both acidic and neutral conditions may be attributed to the cloaked membrane.

These results indicate that LMGNSs could act as a pH-sensitive cargo for drug delivery. The LMGNSs could maintain their original shape for 6 h in the neutral medium (Figure 1(j)). When exposed to acidic media, they transformed and fused with each other (Figure 1(k)).

Due to the asymmetric structure, the LMGNSs can be actuated by the ultrasonic field. Figure 2(a) illustrates the relationship between the speed of the LMGNSs and the ultrasonic frequency with an applied 10 V ultrasound field. The

FIGURE 2: The acoustically propelled motion of the LMGNSs. (a) The relationship between the motion velocity of LMGNSs and frequency of acoustic field at 10 V. (b) Time-lapse image of a LMGNS at an applied voltage of 10 V and an ultrasound frequency of 420 kHz. Inset is fluorescent time-lapse image of a LMGNS under same condition. (c) The time-lapse images of frequency determined direction control of LMGNSs. (d) The direction changes of LMGNSs during frequency changing. The inset images show the LMGNS 2 at 0.83, 0.93, 1.17, and 1.33 s. (e) The relationship between motion velocity LMGNSs and the applied voltage of acoustic field. Scale bars, 20 μm .

velocity of the LMGNSs increased with the frequency increasing from 390 to 417.5 kHz and then decreased as the frequency increased further. Under the frequency ranging from 415 to 425 kHz, the average velocity of LMGNSs could reach over $100 \mu\text{m s}^{-1}$. Figure 2(b) and Video S1 show that the LMGNSs moved approximately in a straight line with an average velocity of $108.8 \pm 7.8 \mu\text{m s}^{-1}$ (15.5 ± 1.1 body s^{-1}) under the ultrasound field with the voltage of 10 V and the frequency of 420 kHz. However, the velocity of the tracer gallium nanospheres was only $4.1 \pm 0.5 \mu\text{m s}^{-1}$. These results indicate that the LMGNSs are driven by the primary acoustic radiation force. Owing to their photoluminescence property, the motion of LMGNSs also can be monitored in real time by fluorescence imaging (Video S2). This is of great significance for the *in vivo* biomedical applications of nanoswimmers.

The ultrasonic frequency can not only regulate the velocity of the LMGNSs but also change their motion direction. As shown in Figure 2(c) and Video S3, the two LMGNSs moved away from each other in opposite directions with an average velocity of $103.5 \mu\text{m s}^{-1}$ under an ultrasound field 10 V, 420 kHz. The velocity of the LMGNSs then dropped dramatically as the frequency shifts gradually in 1 s. Once the frequency reached 410 kHz, both LMGNSs start to move in

reverse directions at a stable velocity of $33.7 \mu\text{m s}^{-1}$. Figure 2(d) shows the direction change of the LMGNSs in Figure 2(c), with a reference direction taken at 0 s. The direction fluctuated with little changes under both frequencies due to the effect of Brownian motion and changed quickly as the frequency shifted at 0.7 s, resulting in a dramatic rotation of 180° for both LMGNSs at 1.3 s. The inset microscopic images show the rotating process of LMGNS 2 at times 0.83, 0.93, 1.17, and 1.33 s. These results are consistent with previous theories that the shift of frequency leads to a change in the distribution of acoustic pressure [45]. There was a high acoustic pressure node between the two particles which propelled the LMGNSs to move away from each other at 420 kHz. As the frequency shifted, the acoustic pressure distribution gradually changed and a low acoustic pressure node formed at 410 kHz, driving the two LMGNSs close together. We also found that the motion velocity of LMGNSs could be regulated by adjusting the ultrasonic voltage. There was a linear relationship between the velocity and the ultrasonic voltage square V^2 (Figure 2(e)).

One of the challenges of synthetic nanoswimmers in biomedical applications is the biofouling effect, which not only increases the viscous resistance of the nanoswimmers but

FIGURE 3: Kinematic analysis of the GNSs and LMGNs in biological media. (a) Schematic illustration of the acoustically propelled motion of LMGNs in blood. (b) The CLSM images of GNSs and LMGNs after cocultured with Rhodamine-labeled BSA for 24 h. The time-lapse images of (c) GNS and (d) LMGN in the serum and blood under the 420 kHz and 10 V. (e) The velocity of GNSs and LMGNs in PBS, serum, and blood media. (f) The mean squared displacement (MSD) and diffusion coefficient of the GNSs and LMGNs in the different solution. All scale bars, $10 \mu\text{m}$.

also induces immune clearance responses [46]. It is well known that leukocytes are natural immune cells that could circulate in the blood for a long time and recognize cancer cells by proteins on their cell membranes [47]. Therefore, we expect that the leukocyte membrane-coated gallium nanoswimmers (LMGNs) could possess the antibiofouling function of leukocytes (Figure 3(a)). To evaluate their antibiofouling capacity, the GNSs and LMGNs were respectively incubated with Rhodamine-labeled bovine serum albumin (Rhodamine-BSA). After incubation for 24 h, the CLSM images show that the red fluorescence signal of GNSs was much higher than that of LMGNs, indicating less Rhodamine-BSA was attached to the surface of LMGNs (Figure 3(b)). For biomedical applications, it is critical to test the propulsion performance of the nanoswimmers in biological environments. Thus, the motion behaviors of the GNSs and LMGNs in the biological fluids (serum and blood) were tested after being incubated in these media for 24 h. As shown in Figures 3(c) and 3(d) and corresponding Video S4, S5, the movement distances of LMGNs in the serum and blood were longer than that of GNSs within the same time. The average speed of the GNSs and LMGNs in different biological media is shown in Figure 3(e). It can be found that the speed of LMGNs in the serum and blood was $52.9 \mu\text{m s}^{-1}$ and $35.6 \mu\text{m s}^{-1}$, respectively, which is significantly higher than that of GNSs ($31.9 \mu\text{m s}^{-1}$ and $20.2 \mu\text{m s}^{-1}$, respectively). The mean squared displacement

(MSD) and the diffusion coefficient (D) show that LMGNs also displayed a higher diffusion coefficient under the same condition (Figure 3(f)). These results indicate that LMGNs have good capacity to resist biological fouling and can move in biological medium for a long time.

The leukocyte membrane coating enables LMGNs to actively recognize cancer cells in a neutrophil-like way [48]; therefore, LMGNs were explored in cancer cell-targeted therapy. Firstly, the capacity of LMGNs for actively recognizing, seeking, and penetrating into the treated cancer cell was evaluated. As shown in Figure 4(a) and the corresponding Video S6, LMGNs were able to recognize the HeLa cell during the ultrasound field-propelled motion. The attachment to the HeLa cell and spinning behavior of the LMGNs were followed by the penetration and internalization into the cell. CLSM images in Figure 4(b) illustrate the position of the LMGNs relative to the HeLa cell. The LMGNs (green) are visualized due to the photoluminescence property of the liquid metal gallium in the 488 nm channel with a laser intensity of 4 mW; meanwhile, DiD was used to label the membrane of the HeLa cell (red). The 3D reconstruction image further demonstrates the intracellular localization of the LMGNs inside the HeLa cell (Figure 4(c)).

The biomedical application potential of LMGNs was then investigated. The LMGNs have a high absorption in the near-infrared region, which enables their utilization as a photothermal therapeutic agent [49, 50]. As Figure 5(a)

FIGURE 4: LMGNSs actively recognize, target, and penetrate HeLa cell. (a) Time-lapse images of acoustically propelled LMGNSs actively seeking and targeting the HeLa cell. Scale bars, $20\ \mu\text{m}$. (b) CLSM images illustrating the internalization of the LMGNSs in the HeLa cell. Scale bars, $10\ \mu\text{m}$. (c) The 3D reconstruction CLSM image in (b). Scale bar, $10\ \mu\text{m}$.

shows, a shape transformation was clearly observed after irradiated by an 808 nm laser at a power of $15\ \text{mW}\cdot\mu\text{m}^{-2}$ for 5 s, and the cell viability was indicated by calcein acetoxy-methyl (Calcein-AM) and propidium iodide (PI). After the laser radiation, the HeLa cell treated by LMGNSs appeared as red fluorescence which confirmed the necrosis of the cell, while the untreated cells kept alive were indicated by the green fluorescence. The capacity of drug transport and release of LMGNSs were then studied. Fluorescent images in Figure 5(b) exhibit the HeLa cell treated with Dox-loaded LMGNSs for 1, 2, and 4 h. We also found that LMGNS-Dox-incubated HeLa cells displayed higher fluorescence intensity than the GNS-Dox-treated group (Figure S5), which indicates that high cancer uptake of LMGNSs-Dox was attributed to the cell membrane camouflaging. It was found that fluorescence intensity of HeLa cells increased by prolonging the incubation time. The cellular uptake amount of free Dox, GNSs-Dox and LMGNSs-Dox was quantitatively evaluated by using flow cytometry. There was a noticeable peak right shift in the LMGNS-Dox-incubated HeLa cell group (Figures 5(c) and S6, relatively). As shown in Figure 5(d), the mean fluorescence intensity result indicates that the cellular uptake to LMGNSs-Dox was increased to 2.6 times by the leukocyte membrane coated after 4 h incubation, further indicating that the cell membranes cloaked with GNSs increased the cancer target efficiency. We further quantified the efficacy difference of these treatments. MTT assay (Figure 5(e)) shows that only 15% HeLa cells survived after the incubation with the LMGNSs-Dox for 4 h. Compared to free Dox and GNS-Dox treatments, LMGSN-Dox treatment displays higher therapeutic efficiency toward cancer cells.

3. Conclusion

We have introduced an acoustically propelled leukocyte membrane-coated gallium nanoswimmer for enhanced photothermal and chemical cancer therapy. The asymmetric needle-like structure and high density allow for powerful propulsion of the LMGNSs. The motion velocity and direction of LMGNSs could be controlled by the voltage and frequency of the applied acoustic field. The integration of the leukocyte membrane enables the LMGNSs with prolonged motion time due to the capability of antibiofouling in the biological medium. Owing to their strong absorptive capacity in the NIR region, excellent drug loading, and pH-responsive release capacity, LMGNSs exhibit a combined photothermal and chemotherapy ability for cancer cells. This LMGNS integrates the capacities of active motion, antibiofouling, cancer cell recognition, imaging, drug delivery, and photothermal cancer treatment, representing a state-of-the-art multifunctional nanoswimmer for the next-generation precision theranostics.

4. Materials and Methods

4.1. Materials. Gallium, aminopropyltrimethoxysilane (APTMS), and carbonylated β -cyclodextrin (β -CD) were purchased from Aladdin. Park Memorial Institute 1640 (RPMI 1640) medium, 1,1'-dioctadecyl-3,3,3',3'-tetramethylindolodicarbocyanine perchlorate (DiD), dimethyl sulphoxide (DMSO), fetal bovine serum (FBS), 3-(4, 5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide solution (MTT), penicillin streptomycin, and 0.25% Trypsin-EDTA were obtained from Life Technologies Corporation; ceramic transducers (H4P101000, $\phi\ 10\ * 2\ \text{mm}$) were purchased from Fukeda.

All scale bars, 20 μ m.

4.2. Preparation of GNSs. To synthesize GNSs, the monodispersed needle-like liquid metal nanoparticles were firstly prepared by a previous report [40]. Then, the as-prepared liquid metal nanoparticles in 0.5 mL ethanol were introduced into 0.5 mL ethanol solution with 10 μ L APTMS with ultrasonic treatment in an ice bath. The APTMS-modified liquid metal nanoparticles were washed using ethanol and translated to the water solution; subsequently, 80 mg carbonylated β -CD

was added with continuous stirring for 24 h in an ice bath. The resulting GNSs were obtained after removing the excess carbonylated β -CD.

4.3. Synthesis of LMGNSs. Leukocyte cells (THP-1) were firstly suspended in a hypotonic dissolution buffer consisting of 0.2 mM EDTA, 1 mM NaHCO_3 , and 1 mM PMSF. After treatment at 4°C overnight, these cells were enucleated for

20 times by using a hand-held Dounce homogenizer. After the above suspension was centrifuged at 3200 g at 4° C for 5 min, the leukocyte membrane precipitate was obtained after centrifugation at 150000 g at 4° C for 1 h. Subsequently, the isolated leukocyte membranes were physically extruded through 1 μ m, 400 nm, 200 nm, 100 nm, and 50 nm polycarbonate membranes for 21 passes. The LMGNs were then fabricated by fusing the leukocyte membrane nanovesicles onto the surface of GNSs following a published protocol [51]. Briefly, the GNSs and leukocyte nanovesicles were mixed and then sonicated by using an Autoscience AS7240AT ultrasonic machine for 2 h in an ice bath. After removing the excess leukocyte membrane nanovesicles, LMGNs were obtained.

4.4. Acoustic Experiments. The acoustic-propelled motion of the LMGNs was conducted by using an ultrasonic setup, which is made of a function generator (Tektronix AFG1062), signal amplifier (Toellner TOE 7607), and ceramic transducer. And the sample cell is a cylinder with a height of 1.5 mm and a diameter of 5 mm, and the ceramic transducer was pasted on the bottom of the sample cell. The LMGNs were incubated in the biological media (water, PBS, serum, and blood) for 24 h, and then a 15 μ L LMGN solution was dropped into the sample cell and covered by a square coverslip. A frequency of 390–450 kHz and 0–10 V voltage were applied to actuate the LMGNs, which was observed by an Olympus optical microscope (OLYMPUS BX53).

4.5. Photothermal Treatment Experiments. The photothermal therapy of LMGNs was observed by the fluorescence microscope (Olympus IX 71). The HeLa cells with LMGNs were irradiated by an 808 nm laser at the power of 15 mW· μ m⁻² for 5 s. Then, the cell viability is determined by adding PI and Calcein-AM. Finally, the resulting fluorescence image was captured under a 488 nm light.

4.6. Flow Cytometry Analysis. The cellular uptake of the various drug-loaded nanoswimmers was evaluated by using the flow cytometry analysis. GNSs-Dox, LMGNs-Dox, and free Dox with a drug concentration of 10 μ g mL⁻¹ was cocultured with HeLa cells with for 1 h and 4 h, respectively. After that, the free Dox and nanoswimmers were removed by washing with PBS solution for 5 times. Then, HeLa cells were harvested, and their fluorescence intensity was tested by flow cytometry (BD FACSAria).

4.7. MTT Assay. To evaluate their anticancer efficiencies, PBS, free Dox, GNSs-Dox and LMGNs-Dox first cocultured with HeLa cells for 1 h and 4 h. Then, a drop of 20 mL MTT solution with the concentration of 5 mg mL⁻¹ was added into the cell culture medium and incubated with HeLa cells for 4 h. After removing the culture medium, 150 mL DMSO was dropped to HeLa cells, and the cell viability of HeLa cells was measured at the absorbance wavelength of 570 nm by using a microplate reader.
