Locally enhanced electric fields produced by high-curvature structures have been reported to boost the charge transport process and improve the relevant catalytic activity. However, no visual evidence has been achieved to support this new electrochemical mechanism. Here, accelerated electrochemiluminescence (ECL) reactions emitting light are visualized for the first time at the heterogeneous interfaces between microbowls and the supporting electrode surface. The simulation result shows that the electric intensity at the interface with a high curvature is 40-fold higher than that at the planar surface. Consequently, local high electric fields concentrate reactive species to the heterogeneous interfaces and efficiently promote the charge transport reactions, which directly leads to the enhancement of ECL emission surrounding the microbowls. Additionally, the potential to induce visual ECL from a ruthenium complex drops to 0.9 V, which further illustrates the promotion of an electrochemical reaction with the aid of an enhanced electric field. This important visualization of electric field boosted electrochemical reactions helps to establish the proposed electron transfer mechanism and provide an alternative strategy to improve electrocatalytic efficiency.

1. Introduction

As heterointerface structures play an important role in reduction of energetic barriers and acceleration of reaction kinetics for electrocatalytic system, a variety of optimal heterostructure materials have been synthesized to improve the performance of electrocatalysts [1–3]. Recently, many strategies have been proposed to fabricate interfaces in heterostructures, including doping of heteroatoms [4, 5], construction of heterostructures with different components [6, 7], and precise design of atomic metal-active sites [8–10]. These studies have suggested that heterogeneous interfaces exhibit particularly electrocatalytic activities because of their high-curvature morphologies, which is highly beneficial for concentrating electric fields that can affect the distribution of ion concentrations and accelerate charge transfer process [11–13]. Therefore, a low overpotential or amplified electrochemical currents would be achievable at these high-curvature sites.

Although many experimental results indicate that a locally enhanced electric field could accelerate an electro-

chemical reaction, visual evidence is needed to establish this novel electrochemical mechanism and directly image these electrochemical active sites. As an emerging electrochemical imaging approach, electrochemiluminescence microscopy has the ability to visualize an electrochemical reaction in situ at the electrode surface with a high spatial resolution [14–16]. When a certain potential is applied to the ECL system, the luminophores undergo electrochemical oxidation or reduction at the electrode surface, which motivates the formation of excited states that emit light [17–19]. Recently, the ECL collected by a charge-coupled device (CCD) has been suggested to be correlated with the electrochemical activity at the single particle level, indicating the high spatial resolution of ECL microscopy technique [20–22]. In contrast to scanning approaches using nanoprobe [23–25], ECL imaging is particularly suitable for visualizing electrochemical reactions at highly curved surfaces with heterogeneous electric fields. The image obtained could provide visual evidence to elucidate the proposed electrochemical mechanism.

In this communication, a heterogeneous interface is designed by loading bowl-like microparticles (referred to as

SCHEME 1: Schematic representation of the electrochemiluminescence imaging. The luminophore $\text{Ru}(\text{bpy})_3^{2+}$ and coreactant TPrA are oxidized at the heterogeneous interface between the microbowls and the ITO supporting electrode with the aid of enhanced electric field, generating the excited state $\text{Ru}(\text{bpy})_3^{2+*}$. The accelerated ECL emission is produced during the relaxation of $\text{Ru}(\text{bpy})_3^{2+*}$ back to the ground state.

“microbowls”) onto the supporting indium tin oxide (ITO) electrode (Scheme 1), where an enhanced electric field is produced at the heterointerface between the microbowl and ITO electrode. The EM-CCD images a bright ECL ring surrounding the microbowl as a result of the accelerated electrochemical reaction from the luminophore at the heterointerface. The COMSOL simulations and experimental results confirm the existence of locally enhanced electric field, which is able to significantly promote the ECL emission.

2. Result and Discussion

2.1. Locally Enhanced Electric Field for Accelerating the Electrochemical Reaction. These microbowls (e.g., Au and Pt) are prepared by using polystyrene (PS) particles as the template (Figure S1). Scanning electron microscopy (SEM) images (Figure S2) confirm that the Au hemispherical shell has a bowl-like structure and a thickness of ~ 60 nm. The outer diameter (OD) of these microbowls is controlled by the size of the PS particles (e.g., the OD is $5.0 \pm 0.12 \mu\text{m}$ using $5 \mu\text{m}$ PS particles). After drop-casting these as-fabricated microbowls onto an ITO slide, over 80% of the microbowls in a face-down configuration make contact between the rim of the bowls and the supporting slide (Figure 1(a) and Figure S2d). The face-down configuration could provide a large contact area that stabilizes the microbowls on the ITO slide. According to the literature and our previous derivation [26, 27], an enhanced electric field is present at the interface between two mediums with different dielectric properties. Therefore, the electric field line around the heterointerface between the microbowl and ITO surface is more intense than that at the planar surface, which increases the electric strength. To support this statement, the potential drop is

simulated using COMSOL software (see Experimental Section). A large potential drop adjacent to the heterointerface between the microbowl and ITO surface is obtained (Figure S4). According to the equation below, an increased potential gradient result in an increased electric intensity at the heterointerface (Figure 1(b)) [28, 29]:

$$E = -\nabla V, \quad (1)$$

where V is the potential and E is the electric strength. The intensity at the heterointerface is ~ 40 -fold larger than that at the planar surface $1.0 \mu\text{m}$ away from the heterointerface (Figure 1(c)), confirming the proposed enhanced electric field at the heterointerface.

Experimentally, the ITO slide loaded with gold microbowls is exposed to 10 mM PBS (pH = 7.2) with 5 mM $\text{Ru}(\text{bpy})_3^{2+}$ and 50 mM TPrA (Figure 1(d)). A periodic switching voltage (-1 V for 0.5 s and increased to $+1.2$ V for 2 s) is applied on the ITO electrode. Under the potential of 1.2 V, $\text{Ru}(\text{bpy})_3^{2+}$ and TPrA are electrochemically oxidized at both the ITO slide and the microbowls emitting ECL. As expected, a visible ECL ring is observed surrounding the microbowl exhibiting an enhanced ECL intensity (Figure 1(e)). The image (Figure 1(f)) that overlaps the bright-field and ECL images confirms that accelerated ECL occurs at the heterointerface with a high electric field. The average ECL intensities at the heterointerface, ITO, and microbowl surface are measured to be 548.1, 128.7, and 177.8 a.u., respectively. The ECL intensity at the gold microbowl is higher than that at the ITO surface, owing to the superior electrocatalytic performance at gold material. In comparison with the ECL signals from the ITO and microbowl, an ~ 4.3 -fold increase in ECL intensity at the heterointerface provides the first visual evidence of an accelerated ECL reaction under a locally enhanced electric field.

2.2. Simulation of the Electrochemical Reaction at the Junction. To further understand this electric field accelerating electrochemical reaction, the concentration distributions from the $\text{Ru}(\text{bpy})_3^{2+}$, $\text{Ru}(\text{bpy})_3^{3+}$, and the ECL profiles at the heterointerfaces are simulated by COMSOL software (more detail in Experimental Section). All the charge transfer reactions and mass transport are considered comprehensively in the system. At an initial potential of -1 V, the concentration of $\text{Ru}(\text{bpy})_3^{2+}$ is slightly higher than that at the planar electrode (Figure 2(a)), which should be ascribed to additional negative surface charges at the heterointerface with a high electric field. Following Pauling’s principle of electroneutrality, electrons stored on the electrode surface from the external circuit are equal to the total number of excess charges in the diffuse layer [30, 31]. Therefore, additional $\text{Ru}(\text{bpy})_3^{2+}$ should be present at the heterointerface, which is similar to the previously reported concentration effect under a high electric field [12]. When the potential is increased to 1.2 V, the oxidation of $\text{Ru}(\text{bpy})_3^{2+}$ and TPrA generates ECL emission. The dynamic simulation displays the consumption of $\text{Ru}(\text{bpy})_3^{2+}$ and the formation of $\text{Ru}(\text{bpy})_3^{3+}$. In particular, less $\text{Ru}(\text{bpy})_3^{2+}$ and more $\text{Ru}(\text{bpy})_3^{3+}$ at the heterointerface are observed than those at

(d) The simulated ECL intensity at the heterogeneous interface after oxidation.

the microbowl and ITO surfaces (Figures 2(b) and 2(c)). Moreover, enhanced ECL emission is obtained at the heterogeneous interface from the simulation (Figure 2(d)). All these experi-

mental and simulation results provide a possible mechanism for the acceleration of the ECL reaction. In summary, an enhanced electric field induces the initial accumulation of

FIGURE 3: ECL images of different microbowls: (a) ECL images of Al and Pt microbowls loaded at the ITO surface; (b) the enhancement ratio of ECL intensity between the heterogeneous interface (with different microbowl materials) and the ITO surface; (c) ECL images of Au microbowls with the size of 12 and 8 μm ; (d) the enhancement ratio of ECL intensity between the heterogeneous interface (with different microbowl size) and the ITO surface; (e) the simulated electric field at the ITO surface with two adjacent microbowls; (f) the bright-field and ECL images from the adjacent microbowls. reactants and additional product generation during the electrochemical reaction, emitting a bright ECL light at the heterointerface.

2.3. Visualization of Accelerated Electrochemical Reaction under Different Conditions. To confirm this visual evidence, the ITO electrode coated with Au microbowls is immersed into PBS solution containing another luminophore, luminol, to initiate the ECL reaction. An obvious blue ECL ring encircles the Au microbowls (Figure S5), whose intensity is ~ 2.45 -fold stronger than that at the surfaces of both the ITO and microbowl. As compared with the enhancement ratio from $\text{Ru}(\text{bpy})_3^{2+}$, the variance in the ECL enhancement from luminol is ascribed to the difference in the ECL efficiencies from these two luminophores. The observation of ECL rings from different luminophores illustrates that various ECL reactions could be accelerated at the heterointerface with an enhanced electric field. Subsequently, different materials (Pt and Al) are used to prepare the microbowls for ECL observation. Red ECL rings with an enhanced intensity are clearly observed around the Pt or Al microbowls in the $\text{Ru}(\text{bpy})_3^{2+}$ and TPrA solutions (Figure 3(a)). The intensities of the ECL rings follow the trend of $\text{Au} > \text{Al} > \text{Pt}$,

which is consistent with the trend of their conductivities (Figure 3(b)). Since a large discrepancy in the conductivity of the two materials at the interface leads to an enhancement in the electric field, the trend in the intensity of the ECL ring conforms to the theoretical expectations. Finally, Au microbowls 8 or 12 μm in size are cast onto the surface of the ITO to study the size-dependent effect on the ECL enhancement (Figure 3(c)). A similarly enhanced ECL is observed from microbowls with different sizes (Figure 3(d)), which indicates that the similar curvature of the contact between the bowl and the supporting ITO might not change significantly the electric field intensity at the interface. Overall, although different microbowl materials and luminophores alter the enhancement ratio of the ECL at the heterointerface, the formation of an increased ECL at this region with a high electric field is clear, supporting the acceleration of an electrochemical reaction under a high electric field.

Interestingly, the location of two adjacent microbowls is found to create a low electric field region between these microbowls. In principle, as the two microbowls gradually approach each other, electrostatic repulsion from the electrons at the bowls occurs, resulting in electric fields with

FIGURE 4: ECL images at different voltages. The false-color ECL images of microbowls at the supporting ITO surface applied with different voltages. The color presents the ECL intensity.

opposite directions. Thus, a weakened electric field should be formed between the microbowls in the vertical direction. To illustrate the distribution of the electric field, the spatial distribution of the local electric field and potential around the two microbowls is simulated (Figure 3(e)). Sparse equipotential lines between the two microbowls are clearly exhibited (Figure S6a). The electric field strength at $1.0\ \mu\text{m}$ away from the microbowl drops from $11\ \text{kV/cm}$ (without an adjacent microbowl) to $0.31\ \text{kV/cm}$ (with an adjacent microbowl) (Figure S6b). Correspondingly, the ECL image (Figure 3(f)) exhibits a defective ECL ring with a gap facing the adjacent microbowls, where a low electric field slows the ECL reaction between $\text{Ru}(\text{bpy})_3^{2+}$ and TPrA. Although a shorter distance between these two microbowls could produce less electric field strength and the resultant slower electrochemical process, the diffusion of electroactive species is also present with a distance of $1\sim 2\ \mu\text{m}$ that prohibits the decrease in ECL intensity. Consequently, a bright ECL ring with the darkest gap is observed with a distance of $1\sim 2\ \mu\text{m}$ between two microbowls. The correlation of the electric field and the ECL intensity provides further visual evidence about the acceleration of an electrochemical reaction by a local electric field.

2.4. Initiate of Electrochemical Reaction at Low Potential. In electrochemistry, the achievement of a low potential to initiate an electrochemical reaction is important in many fields,

such as electrical analysis and energy [32–34]. After validating the acceleration of an electrochemical reaction under an enhanced electric field, the potential to induce the reaction between $\text{Ru}(\text{bpy})_3^{2+}$ and TPrA is attempted to decrease it from 1.2 to 0.9 V. The ECL images (Figure 4) show that the ECL intensities at the Au microbowl and ITO surface decrease with less potential and become almost invisible with a potential of 0.9 V. Some strong ECL spots observed at the ring should be ascribed to the presence of some sharp protrusions at the rim of microbowls (Figure S2d), which lead to the concentrated electric field and the resultant enhanced ECL emission. Excitingly, the ECL ring at the heterointerface is still visible under the potential of 0.9 V, which promotes an electrochemical reaction with the aid of an enhanced electric field. This important observation not only supports the acceleration of an electrochemical reaction by the enhanced electric field but also provides an alternative strategy to improve the electrochemical reaction efficiency.

3. Conclusions

In summary, we provide visual evidence to directly support a new electrochemical mechanism in which a locally enhanced electric field at an electrode surface could accelerate an electrochemical reaction. The heterogeneous distribution of the electric field could be realized by the design of materials with special structures at the supporting electrode. The

establishment of this new mechanism sheds light on the crucial role of the electric field in electrocatalysis. In addition, some electrochemical reactions can be performed at low applied potential by the assistance of an enhanced electric field, promoting the practical application of electrochemistry in relevant fields. More microstructures with different shapes and sizes are being fabricated in the laboratory by changing the topography of the template. The study at these microstructures would solidify the conclusion about accelerated electrochemical reaction under enhanced electric field.

4. Experimental Section

4.1. Chemicals. Ru(bpy)₃Cl₂ and tripropylamine (TPrA) were purchased from Sigma-Aldrich. Colloidal suspension of monodisperse polystyrene (PS) microspheres with different diameters was purchased from Tianjin Beisile Chromatography Technology Development Center (Tianjin, China). Tetrahydrofuran solvent (Shanghai, China) was used to dissolve PS spheres. The sputtering targets (Au, Pt, Al ≥ 99.999%) were obtained from Zhongnuo Advanced Material (Beijing) Technology Corporation. ITO slides (coating thickness, 180 nm; resistance, <10 Ω m⁻²) were purchased from South China Xiangcheng Technology Co., Ltd. All other reagents were of analytical grade and were used without any purification. All aqueous solutions were prepared with ultrapure water obtained from a Milli-Q water purification system.

4.2. Fabrication of Microbowls. Experimental procedures to fabricate monodisperse Au microbowl particles are illustrated in Figure S1. Briefly, ordinary glass slides (8 × 15 mm) were ultrasonically cleaned in ultrapure water and ethanol solution, respectively. Then, the glass substrates were immersed into the piranha solution (concentrated H₂SO₄/30% H₂O₂, 3:1) to render the surface hydrophilic. Hydrophilic glass substrates were placed in a clean dish filled with 5 mL ultrapure water. All PS particles were dispersed in 1-butanol, which were dropped onto the water surface. Then, the monolayer colloidal film was formed on the water surface and was transferred to the glass slide by a peristaltic pump. Subsequently, the PS array particles on the glass slide were coated with gold conductive layer at a certain thickness using sputtering deposition. The gold-coated PS array on the glass slide was put into a 2 mL centrifuge tube filled with tetrahydrofuran solvent. The particles were detached from the glass slide after the sonication for 10 s, and the polystyrene templates were completely dissolved in tetrahydrofuran after 12 h. The microbowls with nanoshells were obtained by centrifugation at 8000 rpm for 10 min. Finally, the microbowls were dispersed with 1 mL of ethanol solution and maintained at 4°C.

4.3. Assembly of the Au Microbowl-Coated ITO Electrode. The purchased ITO electrode was cut into a 1.5 × 2.5 cm rectangular piece with a glass cutter, and these pieces were cleaned ultrasonically in acetone, ethanol, and ultrapure water, respectively. The cleaned ITO pieces were dried with nitro-

gen. Then, the solid-state PDMS O-ring with a diameter of 1.0 cm was prepared by hole punch, which was bonded to the conductive surface of ITO electrode with liquid PDMS. Subsequently, the ITO electrode-bonded PDMS O-rings were dried on a hot plate at 120°C for 2 min to form an electrochemical cell. A 10 μL of ethanol containing ~4 × 10⁴ microbowl particles was added into the electrochemical cell. With the rapid evaporation of the ethanol solvent, the microbowls naturally fell on the surface of the ITO electrode. Finally, the ITO electrode covered with microbowls was dried on the hot plate for the ECL imaging.

4.4. ECL Imaging. The ECL imaging was performed with a three-electrode setup, consisting of a microbowl-coated ITO working electrode, an Ag/AgCl reference electrode (RE), and a Pt-counter electrode (CE). In order to measure ECL, a periodically switching voltage (-1 V for 0.5 s and stepped to 1.2 V for 2 s) was applied on the working electrode in 10 mM PBS (pH = 7.2) containing 5 mM Ru(bpy)₃²⁺ and 50 mM TPrA. The exposure time was set to 2.5 s to collect ECL images, which were recorded by the optical microscopy coupled with a 40x objective and an EM-CCD camera.

4.5. COMSOL Multiphysics Simulations. The COMSOL Multiphysics 5.4 was used to simulate the distribution of electric field and equipotential lines in the junction between gold microbowls and the ITO surface. The electrostatics module was utilized to solve the electric field in the vicinity of the junction under a potential of 1.2 V. The electric field (*E*) was calculated as the opposite gradient of the electric potential *V* as follows: *E* = -∇*V* [12, 28]. The electric conductivity of the gold microbowls and the ITO electrode was taken to be 4.42 × 10⁷ S/m and 2.0 × 10⁵ S/m, respectively [35]. The electrolyte conductivity was assumed to be 10 S/m [36]. Gauss's law was used to compute charge density (*ρ*), according to the equation: *ρ* = ε_rε₀∇·*E*, where ε₀ and ε_r were the dielectric function for a vacuum and materials, respectively [12]. The ε_r equaled 78 for the electrolyte and 1 for gold.

In this work, to simulate the electrochemical reaction in the electrical double layer, an electrochemical reaction cell consisting of gold microbowl, supporting ITO electrode and electrolyte, was fabricated in electrical analysis module of COMSOL software. The boundary and domain settings are shown in Figure S3. The charge transfer reactions took place on the surface of the Au microbowl (domain 3) and supporting electrode surface (domain 1). The homogeneous chemical reactions occurred in the electrolyte (domain 2). In numerical simulation, charge transfer reaction and mass transport were considered in the electrochemical reaction. The mass transport was determined by the Nernst-Planck equation [37]:

$$\begin{aligned} \frac{\partial C_i}{\partial t} + \nabla J_i &= R_i, \\ J_i &= -D_i \nabla C_i - \frac{Z_i F}{RT} D_i C_i \nabla \phi. \end{aligned} \quad (2)$$

The oxidation and reduction of $\text{Ru}(\text{bpy})_3^{2+/3+}$ redox pair follow the Butler-Volmer equation [38].

$$i_{\text{loc}} = Fk_0 \left\{ C_{\text{red}} \exp \left(\frac{1 - \alpha F}{RT} \Delta\varphi \right) - C_{\text{ox}} \exp \left(\frac{-\alpha F}{RT} \Delta\varphi \right) \right\}. \quad (3)$$

Based on the Butler-Volmer equation, current density i_{loc} was the function of heterogeneous reaction rate k_0 , concentration of oxidized/reduced species, and overpotential $\Delta\varphi$. Transfer coefficient α was taken as 0.5. The heterogeneous reaction rate k_0 of the ITO electrode and gold microbowl was taken to be 5×10^{-4} m/s and 1.59×10^{-5} m/s, respectively. To simulate the concentration distribution of the $\text{Ru}(\text{bpy})_3^{2+/3+}$ redox pair at the junction between gold microbowl and ITO electrode, a time-dependent study on transport of diluted species was considered. All reaction equations in Table S1 and parameters in Table S2 were from previous reports [39–41]. According to variables c1–c8 in Table S3, the homogenous and heterogeneous reactions of ECL were modulated in the 2D model fabricated by the COMSOL software.
